14 *This document is a structured, section-by-section summary of the key points argued in the*
15 *companion manuscript, “| Power Analysis for Run-In Clinical Trials under AR(1) and General*
16 *Correlation Structures.” It is provided as a supplementary reading aid and does not stand on*
17 *its own; all notation, derivations, simulation detail, and citations are in the main manuscript.*

18

19 **1 Introduction**

20 **The efficiency of run-in designs is governed by the correlation structure of the**
21 **repeated measurements.**

- 22 • Under compound symmetry the correlation between change scores is constant.
23 • Run-in observations then inform the random slope through simple averaging.
24 • Under AR(1) the correlation decays with separation, so run-in information depends on
25 distance from the treatment period.

*Wertheim School of Public Health, UCSD; ORCID: 0000-0003-1686-4965

This paper extends prior compound-symmetric run-in frameworks to AR(1) residual correlation.

- Paper 1 assumed the rank-one-plus-identity change-score covariance from independent errors.
- Wang (2019) extended run-in to two-period mixed models but kept compound symmetry.
- We instead adopt AR(1) residual correlation with geometric decay in lag.

Existing literature treats autocorrelation and change-score variation but not the run-in setting.

- Winkens (2007) studied optimal designs for autocorrelated data outside the run-in context.
- Diggle and Verbeke give general treatments of longitudinal correlation structures.
- Munoz et al. (1992) embedded compound symmetry and AR(1) in a single damped-exponential family, the natural generalization of the two structures contrasted here.
- Chambless (1993) addressed intra-individual variation in change scores, a concern amplified under AR(1).

The closed-form AR(1) derivation covers a design case the reference longpower toolkit does not.

- Its slope-based closed-form routines assume independent or compound-symmetric residuals.
- Its `power.mmr.ar1()` routine implements the analytic AR(1) formula of Lu, Luo, and Chen (2008), but without run-in or common close observations under a random slope.
- Our formula supplies that case and collapses to the compound-symmetric structure of Paper 1 as $\rho \rightarrow 0$.

1.1 Marginal covariance

The AR(1) change-score covariance loses rank-one structure but the Woodbury reduction survives.

- The matrix R is no longer rank-one-plus-identity, so Sherman-Morrison does not apply.
- The Woodbury identity still reduces the inverse covariance to a scalar inversion.
- This holds because the random-effects covariance G remains scalar.

1.2 Woodbury computation

The Woodbury scalar term persists, but the residual inverse must now be computed differently.

- The correction term H remains a scalar as in Paper 1.
- The residual inverse R^{-1} must be obtained numerically.
- Equivalently it follows from the AR(1) tridiagonal inverse rather than Sherman-Morrison.

62 1.3 Cross-covariance between phase means

63 **A moment-based alternative derives the pre-post variance directly from the phase**
64 **means.**

- 65 • It computes the variance of the test statistic from the moments of the phase means.
- 66 • The run-in mean averages the run-in observations.
- 67 • The treatment-period mean averages the treatment-period observations.
- 68 • The construction follows the summary-measures approach of Frison and Pocock (1992).

69 2 Relationship between the two approaches

70 **The GLS and moment-based approaches target distinct variance quantities.**

- 71 • The GLS variance is the minimum-variance bound under the assumed model.
- 72 • The moment-based variance is that of the simple averaged change-score estimator.
- 73 • The two therefore answer different efficiency questions.

74 **The two approaches do not coincide even without a random slope.**

- 75 • At $\sigma_b^2 = 0$ the GLS estimator still weights observations through the AR(1) residual
76 covariance and targets the slope difference.
- 77 • The moment-based quantity is the variance of the unweighted phase-mean difference, a
78 different estimand.
- 79 • Numerically, at $J_0 = 2$, $J_1 = 2$, $\rho = 0.5$, $\sigma^2 = 1$, $\sigma_b^2 = 0$: GLS 0.636 versus moment-
80 based 1.219.

81 **The moment-based computation serves the simple pre-post estimator, not as a**
82 **bound on the GLS variance.**

- 83 • It requires no specification of the random-slope variance.
- 84 • It is the exact variance of the unweighted pre-post difference an analyst might report
85 without fitting a mixed model.
- 86 • Because the estimands differ, its ratio to the GLS variance is descriptive, not an efficiency
87 bound.

88 3 Discussion

89 **The autocorrelation structure matters for run-in designs only when the autocor-**
90 **relation is weak relative to the random-slope signal.**

- 91 • When the slope-to-noise ratio is large, the random-slope term dominates the change-
92 score covariance and the residual correlation structure is second order.
- 93 • The AR(1) and compound-symmetry variances then differ negligibly, and the simpler
94 Paper 1 formula suffices.

- The two structures diverge most when the slope-to-noise ratio is small and run-in observations are distant from randomization.

At a matched nominal ρ , compound symmetry is generally conservative, with a narrow anticonservative corner.

- Positive serial correlation reduces the residual variance of every change score, so the AR(1) variance falls below the compound-symmetric value for most designs.
- The discrepancy grows with ρ ; near $\rho = 0.95$ the AR(1) variance can fall below one tenth of the compound-symmetric value.
- The exception is large J_0 at small ρ , where distant run-in observations lose information and compound symmetry understates the variance by at most about 6%.

The numerical comparisons give a practical decision rule for when the simpler formula is safe.

- At a matched nominal ρ , the compound-symmetry formula of Paper 1 is a conservative and convenient default for most designs.
- With many run-in observations and low expected autocorrelation, the AR(1) formula should be used directly; the compound-symmetric formula can understate the variance by up to about 6% there.
- When ρ is uncertain, evaluating the AR(1) formula over a plausible range of ρ and taking the largest variance is a safe default.

4 Data availability statement

The implementing package, tests, and bibliography are openly available in the project repository.

- The package implements the AR(1) variance formulas.
- Validation tests and the shared four-paper bibliography are included.
- Specific paths appear in the Reproducibility section below.

5 Reproducibility

The manuscript was rendered with R 4.4.x using a small set of principal packages.

- The in-package source supplies the AR(1) machinery.
- Testing uses the tinytest harness.
- The manuscript build uses rmarkdown and bookdown.

All reported quantities are deterministic.

- Given fixed inputs the variance formulas exercise no random-number generator.
- No Monte Carlo computation appears in this manuscript.
- Re-running the chunks therefore reproduces every table and figure exactly.

129 **All source, companion manuscripts, and bibliography reside at documented repos-**
130 **itory paths.**

- 131 • The R package source is in the package source directory.
- 132 • The companion manuscripts for Papers 1, 3, and 4 have their own analysis subdirectories.
- 133 • This manuscript source and the shared bibliography reside in the correlation-paper di-
- 134 rectory.
